du Lac, Angers, France**(v1.0 released January 2013)*

This paper presents a set membership method (named Interval Analysis Localization) to deal with the global localization problem of mobile robots. By using a LIDAR (**L**ight **D**etection **A**nd **R**anging) range sensor, the odometry and a discrete map of an indoor environment, a robot has to determine its pose (position and orientation) in the map without any knowledge of its initial pose. In a bounded error context the IAL (Interval Analysis Localization) algorithm searches a set of boxes (interval vector), with a cardinality as small as possible that includes the robot's pose. The localization process is based on constraint propagation and interval analysis tools, such as bisection and relaxed intersection. The proposed method is validated using real data recorded during the CAROTTE challenge, organized by the French ANR (National Research Agency) and the French DGA (General Delegation of Armament). Interval Analysis Localization is then compared with the well known Monte Carlo Localization showing weaknesses and strengths of both algorithms. As it is shown in this paper with the IAL algorithm, interval analysis can be an efficient tool to solve the global localization problem.

Keywords: interval analysis; bounded errors; global localization; mobile robots; kidnapping

1. Introduction

Robot localization is one of the most important issue of mobile robotics [1, 2]: a robot has to know its location to be able to perform navigation tasks. The localization problem can be divided into two categories: the pose tracking and the global localization. In the pose tracking problem a robot has to find its new pose using the knowledge of its initial pose. Usually this is done in real time while the robot is exploring its environment. In the global localization problem a robot has to find its pose without the knowledge of its initial pose.

Most of the proposed solutions to localize a robot are based on probabilistic estimation techniques (see [3, 4]). The Kalman Filter [5, 6] and its improvements [7] are used for the pose tracking problem [8] and more precisely for the SLAM problem (see [9, 10]). Particle filters [11] with for example the Monte Carlo algorithm [12] and its spin-off [13, 14] are used to deal with the global localization problem.

In this paper a set membership approach, named **I**nterval **A**nalysis **L**ocalization (IAL) algorithm, will be considered for the global localization problem and compared to a **M**onte **C**arlo **L**ocalization (MCL) algorithm. Set membership localization algorithms already exist. Using a **S**et **I**nversion **V**ia **I**nterval **A**nalysis (SIVIA) approach [15] and an environment vectorization [16] for example, or combining stochastic and set membership tools [17].

The presented approach has several advantages over the existing set-membership localization methods.

*Corresponding author. Email: remy.guyonneau@univ-angers.fr

First, IAL algorithm considers a binary grid map, obtained for example by using classical SLAM techniques, and do not need environment vectorization, unlike [16]. All the maps presented in Section 4 have been entirely provided by actual robots: they are sets of points and did not have any human operator modification (as it can be done in [15] to notify seamarks). It can be noticed that, even if we chosen probabilistic SLAM techniques to provide the maps, it exists set-membership SLAM [18]. By using a grid map, the algorithm computation is independent over the number of obstacles of the environment. Which is not the case for vectorized environments. Furthermore it can be noticed that no landmarks are considered as this paper does not associate occupancy grid maps to landmark maps. Such differentiation can be found in [19–21].

The presented method is a full deterministic and repeatable set membership method that does not consider any stochastic tool, unlike [17]. Thus the results of the localization process are obtained in a guaranteed way, according to a fixed number of outliers (measurements that are not consistent with the problem). This guarantee (that the robot’s pose is contained in the algorithm results) is obtained by considering a bounded error context and using interval analysis.

Then, the proposed method can be implemented fully on-board, as it is presented in Section 4.3, and do not need any distant server to process the localization. Finally, this method can deal with the kidnapping problem, i.e. detect a kidnapping situation and then process a global localization.

The proposed algorithm combined two interval tools: contraction and bisection. First the localization problem is seen as a **C**onstraint **S**atisfaction **P**roblem (CSP). Using contractors, the set of feasible poses is reduced (contracted). Then when the CSP failed to contract the domains, a bisection is performed. Thus it is possible to improve the precision of the CSP results.

The paper is organized as follows. First the considered global localization problem is presented in Section 2. The IAL algorithm is detailed in Section 3 and experimental results are presented in Section 4. Finally Section 5 compares the IAL and the MCL algorithms and Section 6 concludes this paper.

2. The Global Localization Problem

This section presents the considered localization problem.

2.1 The Robot

A mobile wheeled robot (depicted in Figure 1) with a range sensor is considered. This system is characterized by the following discrete time dynamic equations:

$$\mathbf{q}(k+1) = f(\mathbf{q}(k), \mathbf{u}(k)), \quad (1)$$

$$\mathbf{y}(k) = g_{\varepsilon}(\mathbf{q}(k)). \quad (2)$$

Figure 1. Robot used during the CAROTTE challenge.

The robot's pose $\mathbf{q}(k) = (x_1(k), x_2(k), \theta(k))$ is defined by its location $\mathbf{x}(k) = (x_1(k), x_2(k))$ and its orientation $\theta(k)$ in the environment, denoted ε , at discrete time k . The environment $\varepsilon \in \mathbb{R}^2$ is a two dimensional domain where the robot moves. The function f characterizes the robot's dynamic and the vector $\mathbf{u}(k)$ corresponds to the control vector at time k .

Here is the dynamic function we have considered for our experimentations:

$$\begin{pmatrix} x_1(k+1) \\ x_2(k+1) \\ \theta(k+1) \end{pmatrix} = \begin{pmatrix} x_1(k) \\ x_2(k) \\ \theta(k) \end{pmatrix} + \begin{pmatrix} \sin(\theta(k))\Delta_{x,k} \\ \cos(\theta(k))\Delta_{x,k} \\ \Delta_{\theta,k} \end{pmatrix}, \quad (3)$$

with $\Delta_{x,k}$ the translation done by the robot between the time k and $k+1$, and $\Delta_{\theta,k}$ the rotation done by the robot between the time k and $k+1$. Those two values are estimated by the odometry's sensors.

The vector $\mathbf{y}(k) = (y_1(k), \dots, y_n(k))$ is the vector of measurements. The function $g_\varepsilon()$ is not known, as it strongly depends on the environment, which is not known perfectly but approximated by a grid map (Section 2.2). However it can be noticed that $\mathbf{y}(k)$ depends on the robot pose $\mathbf{q}(k)$ and the environment ε . In fact, a measurement y_i corresponds to the distance into the direction γ_i between the robot and the first obstacle in ε (Figure 2).

Figure 2. Sensor measurements $\mathbf{y}(k) = (y_1(k), \dots, y_n(k))$. The maximal range of the sensor is denoted y_{max} .

2.2 The Environment

Figure 3. The environment of the CAROTTE challenge.

The environment ε where the robot is moving is approximated by an occupancy grid map [4]. Figure 3 depicts an example of indoor environment. The grid map, named \mathbb{G} , is composed of $n \times m$ cells (i, j) and at each cell (i, j) is associated $g_{i,j} \in \{0, 1\}$:

$$g_{i,j} = \begin{cases} 0 & \text{if the cell corresponds to an obstacle-free subspace of } \varepsilon, \\ 1 & \text{else.} \end{cases} \quad (4)$$

\mathbb{G} is a discrete version of ε . Figure 4 represents an example of occupancy grid map with 35×38 cells.

Figure 4. Example of occupancy grid map. White cells represent free spaces.

2.3 The Objective

The objective of the global localization problem is to find $\mathbf{q}(k)$, the pose of the robot at discrete time k , without any information about the initial pose $\mathbf{q}(0)$. This is done by using the sensor data $\mathbf{y}(0), \dots, \mathbf{y}(k)$, the control data $\mathbf{u}(0), \dots, \mathbf{u}(k-1)$ (estimated by the odometry), and the grid map \mathbb{G} .

3. Interval Analysis Localization, a Deterministic Approach

The proposed method uses interval analysis and Constraint Satisfaction Problem (CSP) tools to solve the global localization problem. This section presents basics of those tools and then presents the IAL algorithm.

3.1 Interval Analysis Introduction

An *interval vector* [22], or a *box* $[\mathbf{q}]$ is defined as a closed subset of \mathbb{R}^n : $[\mathbf{q}] = ([x_1], [x_2], \dots) = ([x_1, \bar{x}_1], [x_2, \bar{x}_2], \dots)$.

The size of a box is defined as

$$size([\mathbf{q}]) = (\bar{x}_1 - x_1) \times (\bar{x}_2 - x_2) \times \dots,$$

For instance $size([2, 5], [1, 8], [0, 5]) = 105$.

It can be noticed that any arithmetic operators such as $+$, $-$, \times , \div and functions such as exp , sin , sqr , $sqrt$, ... can be easily extended to intervals, [23].

A Constraint Satisfaction Problem (CSP) is defined by three sets. A set of variables \mathcal{V} , a set of domains \mathcal{D} for those variables and a set of constraints \mathcal{C} connecting the variables together.

Example of CSP:

$$\left\{ \begin{array}{l} \mathcal{V} = \{x_1, x_2, x_3\} \\ \mathcal{D} = \{x_1 \in [7, +\infty], x_2 \in [-\infty, 2], x_3 \in [-\infty, 9]\} \\ \mathcal{C} = \{x_1 = x_2 + x_3\} \end{array} \right\}. \quad (5)$$

Solving a CSP consists into reducing the domains by removing the values that are not consistent with the constraints. It can be efficiently solved by considering interval arithmetic [24]. For

the previous example:

$$\begin{aligned}
x_1 = x_2 + x_3 &\Rightarrow x_1 \in [x_1] \cap ([-\infty, 2] + [-\infty, 9]) \\
&\Rightarrow x_1 \in [7, +\infty] \cap [-\infty, 11] = [7, 11] \\
x_2 = x_1 - x_3 &\Rightarrow x_2 \in [x_2] \cap ([7, 11] - [-\infty, 9]) \\
&\Rightarrow x_2 \in [-\infty, 2] \cap [-2, +\infty] = [-2, 2] \\
x_3 = x_1 - x_2 &\Rightarrow x_3 \in [x_3] \cap ([7, 11] - [-2, 2]) \\
&\Rightarrow x_3 \in [-\infty, 9] \cap [5, 13] = [5, 9]
\end{aligned}$$

The solutions of that CSP are the following contracted domains $[x_1]^* = [7, 11]$, $[x_2]^* = [-2, 2]$ and $[x_3]^* = [5, 9]$.

Later the localization problem will be expressed as a CSP.

3.2 The IAL algorithm

A bounded error context is considered for the global localization problem presented in Section 2. In other words it is assumed that all the measurements have a bounded error. For instance, the lidar sensor URG-30LX has a $\pm 5\text{cm}$ measurement accuracy¹ [25]. Thus a guaranteed interval $[y_i(k)]$ can be associated to each measurement $y_i(k)$, according to the sensor accuracy. For example, by considering a guaranteed maximal range error ε_y it is possible to compute an interval $[y_i(k)] = [y_i(k) - \varepsilon_y, y_i(k) + \varepsilon_y]$ that contains the distance between the robot and the detected obstacle, in a guaranteed way. It can be noticed that all the measurements that are not consistent with this bounded error context are considered as outliers. The same idea applies to the odometry sensors.

In this context, the IAL algorithm is able to find a list $\mathcal{L}_k = \{[\mathbf{q}(k)]\}$, with $[\mathbf{q}(k)] = ([x_1(k)], [x_2(k)], [\theta(k)])$, that includes the robot pose $\mathbf{q}(k)$, $\mathbf{q}(k) \in \mathcal{L}_k$. As it is assumed that no information are available about the initial pose $\mathbf{q}(0)$, the initial list \mathcal{L}_0 is initialized with a box $[\mathbf{q}(0)]$ that contains all the possible poses for the robot: all the environment for the position and all the possible orientations.

The IAL algorithm (Algorithm 1) input \mathcal{L}_{k-1} is a set of boxes that contains the estimations of the previous pose of the robot. This set may contain only one box. This algorithm has three important steps.

Algorithm 1: Interval Analysis Localization

Data: $\mathcal{L}_{k-1}, [\mathbf{y}(k)], [\mathbf{u}(k-1)]$

```

1  $\mathcal{L}_k = \emptyset;$ 
2 while  $\mathcal{L}_{k-1} \neq \emptyset$  do
3    $[\mathbf{q}(k-1)] = \mathcal{L}_{k-1}.pop\_back();$ 
4   update  $[\mathbf{q}(k-1)]$  to  $[\mathbf{q}(k)]$  according to  $[\mathbf{u}(k-1)];$ 
5   contract  $[\mathbf{q}(k)]$  by using  $[\mathbf{y}(k)]$  and  $\mathbb{G};$ 
6   if  $size([\mathbf{q}(k)]) > \xi$  then
7     bisect  $[\mathbf{q}(k)]$  into  $[\mathbf{q}_1(k)]$  and  $[\mathbf{q}_2(k)];$ 
8      $\mathcal{L}_k.push\_back([\mathbf{q}_1(k)]);$ 
9      $\mathcal{L}_k.push\_back([\mathbf{q}_2(k)]);$ 
10  else
11    if  $[\mathbf{q}(k)] \neq \emptyset$  then
12       $\mathcal{L}_k.push\_back([\mathbf{q}(k)]);$ 

```

Result: $\mathcal{L}_k.$

¹http://www.hokuyo-aut.jp/02sensor/07scanner/utm_30lx.html

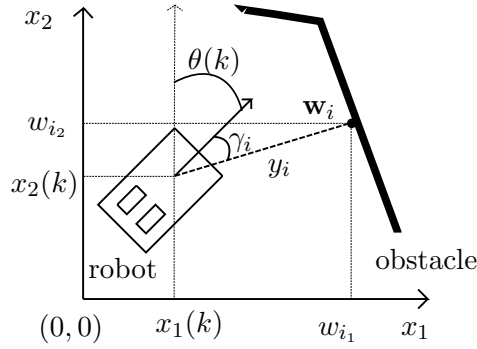

Figure 5. \mathbf{w}_i , the coordinates of the obstacle detected by y_i in the map's frame.

First, line 4, the prediction step. The pose at time k is evaluated from the pose at time $k - 1$ by using Equation (1). The computation $[\mathbf{q}(k)] = f([\mathbf{q}(k - 1)], [\mathbf{u}(k - 1)])$ is done using interval arithmetic.

Then, line 5 corresponds to the contraction step. The measurements $\mathbf{y}(k)$ and an approximation (g_ε) of the observation function g_ε are used to contract the boxes (pose estimations): the idea is to evaluate $\{\mathbf{q}(k) | g_\varepsilon(\mathbf{q}(k)) = \mathbf{y}(k)\}$.

As ε is approximated by \mathbb{G} , IAL algorithm searches $\{[\mathbf{q}(k)] | g_\varepsilon([\mathbf{q}(k)]) = [\mathbf{y}(k)]\}$. This problem is seen as a CSP with the variables $\mathbf{q}(k), \mathbf{y}(k)$, the domains $[\mathbf{q}(k)], [\mathbf{y}(k)]$ and constraints built with the measurements $\mathbf{y}(k)$ and the map \mathbb{G} . To be compared with the map, the measurements $[y_i]$ are converted to obstacle coordinates $[\mathbf{w}_i] = ([w_{i1}], [w_{i2}])$ in \mathbb{G} 's frame, according to $[\mathbf{q}(k)]$ and γ_i , as depicted in Figure 5. An example of contraction using one measurement is presented in Figure 6. Note that

$$[\mathbf{w}_i] = \begin{pmatrix} [w_{i1}] \\ [w_{i2}] \end{pmatrix} = \begin{pmatrix} [y_i] \sin([\theta(k)] + [\gamma_i]) + [x_1(k)] \\ [y_i] \cos([\theta(k)] + [\gamma_i]) + [x_2(k)] \end{pmatrix}, \quad (6)$$

with $[\mathbf{q}(k)] = ([x_1(k)], [x_2(k)], [\theta(k)])$ the current evaluation of the robot's pose.

Finally the last step of the IAL is the bisection line 7. If a contracted box $[\mathbf{q}(k)]$ is bigger than the minimal size ξ , $[\mathbf{q}(k)]$ is bisected into two boxes $[\mathbf{q}_1(k)]$ and $[\mathbf{q}_2(k)]$ such as $size([\mathbf{q}_1(k)]) = size([\mathbf{q}_2(k)])$ and $[\mathbf{q}_1(k)] \cup [\mathbf{q}_2(k)] = [\mathbf{q}(k)]$. This bisection step is needed to avoid fixed points in the CSP. A fixed point is reached when the CSP can not contract the domains any more. A way to avoid this, is to bisect the box and then process the CSP over the two bisected sub-boxes.

As it can be noticed in line 11, bisected boxes that are not consistent with the localization problem are removed from the final solution (more precisely, they are not added to the solution set). Note that outliers are handled using relaxed intersection [26]. Considering n_o outliers over n measurements, the contraction is done assuming that at least $n - n_o$ measurements have to intersect an obstacle in the map.

A kidnapping situation is detected when the resulting list of the algorithm \mathcal{L}_k is empty (too many measurements are not consistent with the current pose estimation \mathcal{L}_{k-1} and the map). When this occurs, the algorithm has to be initialized with all the possible poses (restart a global localization process over the entire environment).

This algorithm can be divided into two main steps: prediction and correction. During the prediction step (update $[\mathbf{q}(k - 1)]$ to $[\mathbf{q}(k)]$ according to $[\mathbf{u}(k - 1)]$) the consuming computation is linear over the number of boxes. The correction step is the most consuming part. The bisection steps are known to have a complexity that is exponential in the number of parameters [27]. On the other hand, the contraction step computation is linear over the number of boxes. It can be concluded that the IAL algorithm is globally linear over the number of boxes.

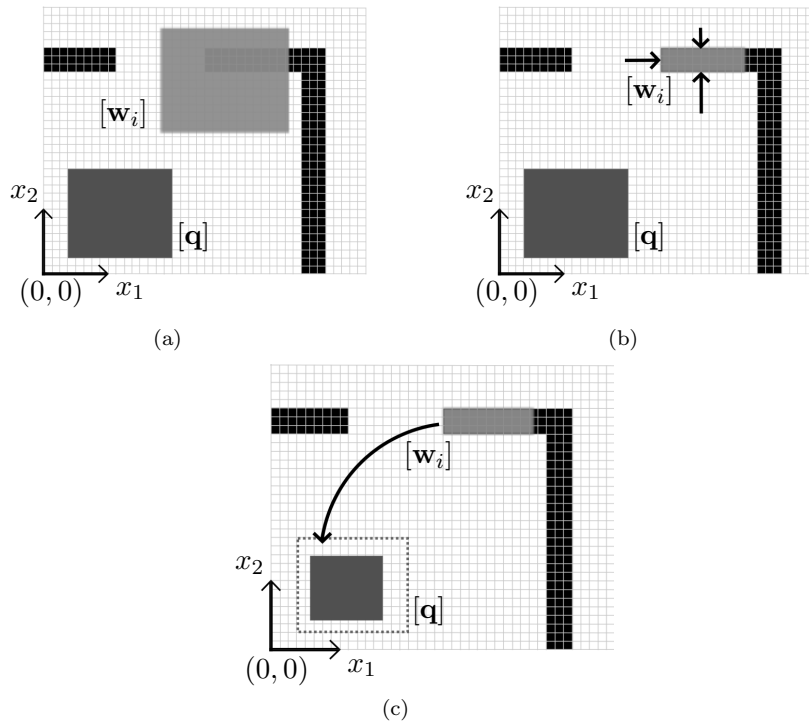

Figure 6. Example of contraction. In Figure 6(a) there is a grid map G (each black cell value is 1). The box $[w_i]$ (light grey) is a guaranteed evaluation of the measurement w_i according to $[q]$ (dark grey) and $[y_i]$. By using the constraint *a measurement has to intersect an obstacle in the map* the domain $[w_i]$ is contracted (Figure 6(b)) and then by using another constraint (*the distance between the robot and the detected obstacle is $y_i \in [y_i]$*) it is possible to contract the domain $[q]$ (Figure 6(c)).

4. Experimental Results

In the following the IAL algorithm is validated with experimentations. First the method is tested by using a distant server to compute the robot localization.

The computer used to process those experimentations has the following specifications:

Memory: 2,0 GiB,
Processors: Intel(R) Core(TM) CPU 6420 @ 2.13GHz.

Then, the algorithm is implemented into a MiniRex robot (Figure 1), and all the computation are done on-board, without considering any distant server.

4.1 The LORIA arena (distant server)

An actual $10\text{m} \times 4.7\text{m}$ indoor environment is considered (Figure 7(a)). By using SLAM techniques a map of this environment is built, Figure 7(b). The objective of the experimentation is to test the IAL algorithm in a real context: map with imperfections and non filtered data provided by an actual sensor. Note that the map has $2\text{cm} \times 2\text{cm}$ grid cells.

Static global localizations are performed at 33 different locations all over the environment, Figure 7(b). Note that for those experimentations, the robot is localized without moving. The measurement accuracy is assumed to be $\pm 5\text{cm}$, i.e, to each measurement $y_i(k)$ the following interval is associated $[y_i(k) - 5\text{cm}, y_i(k) + 5\text{cm}]$.

The results of those global localizations are summarised in Table 1.

The execution time evolves between 21 and 45.5 seconds. This is due to the first iteration of the algorithm which starts with all the environment as possible position and all the possible orientation $([0, 2\pi])$. The first iteration corresponds to the worst case of the localization process

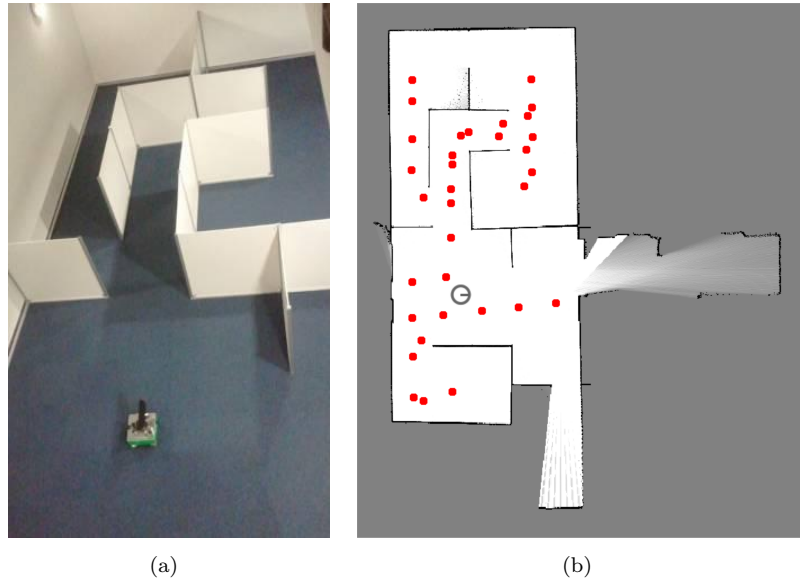

Figure 7. Figure 7(a) represents the experimental environment. Figure 7(b) represents the considered map obtained by performing a SLAM algorithm. White cells represent free spaces in the environment, black cells represent obstacles and grey cells represent unexplored spaces. Note that the grey circle in Figure 7(b) corresponds to the pose of the robot depicted in Figure 7(a) and the filled points correspond to the 33 performed global localizations.

Table 1. Results of the 33 successful global localizations (data of the first iteration)

	Average	Best	Worst	Unity
Execution time	33.4	21	45.5	seconds
Precision of x_1	± 37.2	± 18.1	± 122.1	mm
Precision of x_2	± 32.7	± 16.5	± 51.5	mm
Precision of θ	± 2.75	± 0.55	± 12.2	degrees

(the biggest domain).

Note that, to evaluate the precision of the solution, the hull of the results is processed (it corresponds to the smallest box that contains all the resulting boxes). Then the precision is defined by the size of the dimensions of this hull.

4.2 The CAROTTE arena (distant server)

The following data (map and sensor measurements) were recorded during the CAROTTE challenge in June 2011, by the CARTOMATIC¹ team.

The considered environment, Figure 3, is a 20m \times 20m indoor environment. The objective of the following experimentation is to test the IAL algorithm with a larger and a worse map than the previous experimentation. The considered map is depicted in Figure 8.

Even in those conditions the IAL algorithm is robust enough to provide a localization. Here are the results of a performed global localization (Figure 9):

- Execution time: 28s,
- Precision of x_1 : ± 114.2 mm,
- Precision of x_2 : ± 105.8 mm
- Precision of θ : $\pm 2, 87$ deg

¹<http://5lair.free.fr/Projects/Cartomatic/>

Figure 8. A map of the CAROTTE arena, obtained during the contest. This map was generated with a SLAM algorithm using LIDAR (LIght Detection And Ranging) scans.

Figure 9. The result of a global localization. The grey cells correspond to the obstacles in the map and the black points correspond to the data set used to perform the localization. The black circle corresponds to a solution $\mathbf{q}(k) \in [\mathbf{q}(k)]$ of the global localization result.

4.3 Implementation into a MiniRex

Then we have implemented the localization algorithm into a MiniRex robot. The objective here is to prove that the algorithm can be used in a real mission, considering the moving of the robot (the two previous experimentations processed static localizations). The map presented in this section was obtained by performing a SLAM technique before the localization process. It can be noticed that the LIDAR sensor measurements are used without any filtering.

A global localization in a symmetrical environment (Figure 10) is performed. The robot has been placed into an ambiguous configuration in order to test the behaviour of the algorithm in this case.

The considered map is presented in Figure 10. The initial evaluation of the robot's pose is a $26\text{m} \times 4\text{m} \times 360\text{deg}$ box. This box is represented in the first picture of Figure 11.

Figure 11 presents the initial knowledge of the localization problem and 7 iterations of the localization process. It can be noticed that, because of the symmetries of the environment, the result of the first iteration (second picture) corresponds to two distinct sets of boxes. This ambiguity is solved from the second iteration (third picture), as soon as the robot moves and gets new sensor measurements.

The final result of the experimentation (last picture of the Figure 11), is a $42\text{cm} \times 15\text{cm} \times 7\text{deg}$ box, for a total moving of 12m. The computation time of the first iteration (the most expensive in term of computation time) is about 26 seconds. It can be noticed that those results are closed to the ones presented previously with a distant server.

Figure 10. The environment and its considered map for the global localization experimentation.

5. Comparison Between IAL and MCL

In this section the IAL algorithm is compared with a classic Monte Carlo Localization (MCL) algorithm.

5.1 Monte Carlo Localization

A probabilistic approach for the global localization problem is to compute a probability distribution over all the possible poses of the robot in the environment (Markov localization, [28]). This distribution, called $Bel(\mathbf{q}(k))$, expresses the robot's *belief* for being at the pose $\mathbf{q}(k)$. $Bel(\mathbf{q}(0))$ represents the initial state of knowledge. MCL method [29] represents this belief by maintaining a set of m particles $\mathbb{S}(k) = \{s_1(k), s_2(k), \dots, s_m(k)\}$, drawn from it. A particle $s_i(k)$ is defined by its pose $\mathbf{q}_i(k) = (x_{1_i}(k), x_{2_i}(k), \theta_i(k))$ and a score $q_i(k)$ corresponding to the likelihood of obtaining the data set $\mathbf{y}(k)$ from the pose $\mathbf{q}_i(k)$. The initial belief $Bel(\mathbf{q}(0))$ is represented by a set of particles $\mathbb{S}(0)$ drawn according to an uniform distribution all over the considered environment.

To update the belief, two probabilistic models are used: a motion model to consider the control data and a perception model to exploit the sensor data. The robot motion is modelled by the conditional probability $p(\mathbf{q}(k)|\mathbf{q}(k-1), \mathbf{u}(k))$ and the sensor measurements by the probability $p(\mathbf{y}(k)|\mathbf{q}(k))$.

The MCL algorithm, Algorithm 2, has two important steps. First a re-sampling phase using the motion model, lines 2 and 3, that creates a new set of particles $\mathbb{S}(k)$ according to the previous step $\mathbb{S}(k-1)$ and the control vector $\mathbf{u}(k)$. The second step is the update of the new particle scores $q_i(k)$ using the data from the sensor $\mathbf{y}(k)$ and the sensor model.

Algorithm 2: Monte Carlo Localization

Data: $\mathbb{S}(k-1), \mathbf{y}(k), \mathbf{u}(k)$

1 **for** $i = 1$ **to** m **do**

2 generate random s from $\mathbb{S}(k-1)$ according to $q_1(k-1), \dots, q_m(k-1)$;

3 generate random $s' \sim p(s'|s, \mathbf{u}(k))$;

4 $q_{s'} = p(\mathbf{y}(k)|s')$;

5 add $\langle s', q_{s'} \rangle$ to $\mathbb{S}(k)$;

6 **normalize** the importance factors $q_{s'}$ in $\mathbb{S}(k)$;

Result: $\mathbb{S}(k)$.

Figure 11. The initial data of the localization problem (first picture), and the seven iterations processed by the IAL algorithm (the first picture correspond to $k = 0$ and the last one to $k = 7$). It can be noticed that the robot does not move between the times $k = 0$ and $k = 1$.

5.2 Computation time

From the experimental results presented in Section 4, it appears that the first iterations of the IAL algorithm cost a large computation time.

On the other hand, when the domain has been significantly reduced, the IAL algorithm computation time is comparable to the MCL algorithm.

In the following the computation time of a localization with a smaller domain is tested (a $50\text{cm} \times 50\text{cm} \times 10\text{deg}$ initial box is considered). The experimentation considers a $10\text{m} \times 10\text{m}$ simulated environment (Figure 12), 36 measurements for each iteration (5 outliers), and a box $[\mathbf{q}(0)]$ with a size $1\text{m} \times 1\text{m} \times 10\text{deg}$. Here are the average results of 13 successive localization iterations:

- MCL (5000 particles)

Figure 12. A simulated environment: the black pixels represent the grid map.

- Execution time: 0,07s.
- IAL
 - Execution time: 0,06s.

It appears that in this case IAL and MCL have the same computation time. It can be noticed that the considered odometry error corresponds to 10% of the moving of the robot.

When considering an entire exploration mission, the robot is more often localizing itself considering its previous pose than performing a global localization over all the environment. In fact, the worst case of the localization corresponds to the beginning of the mission and the recovering after each kidnapping.

Example: Considering an exploration mission of 4000s in the LORIA arena presented in Section 4.1. Assuming that during this mission 4 kidnappings were performed, using the IAL method the mission time would be increased of $33.4s + 4 \times 33.4s = 167s$, with 33.4s the average localization time observed in this environment (Table 1). This increase corresponds to the cost of the first localization adding to the four kidnapping recoveries. That would lead to a 4.2% increase of the computation time over the entire mission compared to a MCL approach. In those conditions the computation time of both methods are similar.

Furthermore, the IAL algorithm can process a static localization (without moving the robot), whereas the MCL algorithm uses the moving of the robot to avoid, for example, local minima. In the same simulated environment (Figure 12), we have performed static localizations. It appears that with 10000 particles, without moving the robot, MCL converge to a wrong solution 40% of the time. On the other hand, by moving the robot, MCL managed to localize the robot 100% of the time. Thus the moving time of the robot should be added to the MCL computation time, reducing the computation time difference of the two algorithms. It can be noticed that IAL algorithm also uses the moving of the robot in order to deal with the symmetries in the environment. However, even if the robot does not move, the solution of the localization is contained into the IAL localization results, which is not the case for the MCL localization (with not enough particles). Considering the environment presented in Figure 12, as it does not have symmetries, by using the parameters presented previously, the IAL algorithm manages to localize the robot all the time (without moving).

5.3 Local/Global minima

An obvious weakness of the Monte Carlo algorithm is that it can be stocked in a local minima and do not converge to the expected solution. For example it is the case when there is too few particles. In practice with enough particles the MCL manages to find the global minimum.

A question can be asked, however. Is the global minimum the solution of the localization problem? It is when considering a perfect world (perfect sensors, no outlier), but as soon as there are outliers in the data set, this assumption is not verified any more.

Figure 13(a) represents a simulated pose of a robot in an environment. As it can be seen 8 sensor measurements are outliers. In this case, the best possible score does not correspond to the

robot's pose. In other words, the pose $\mathbf{q}_{best}(k)$ that maximises the probability $p(\mathbf{y}(k)|\mathbf{q}_{best}(k))$ is not the solution of the localization problem. For example Figure 13(b) represents a pose with a better score than the robot's pose.

In those conditions the MCL algorithm does not converge to the expected pose while the IAL algorithm still returns a set that contains the solution (see Figures 14(b) and 14(a)). It exists MCL ameliorations with random sampling to recover from those kind of situations [30] but if this situation occurs during all the localization process, the MCL algorithm and its ameliorations will not converge to the actual localization.

Figure 13. Figure 13(a) represents the considered map (black pixels), sensor data set (light grey pixels), with 8 outliers, and robot's pose (black circle). Figure 13(b) represents a pose with a better score than the expected one.

Figure 14. Figure 14(a) represents the IAL results and Figure 14(b) the MCL results (the grey shapes). The crosses correspond to the expected result. Note that the best particle of the MCL algorithm is the one depicted in Figure 13(b). In those conditions MCL fails to estimate the robot's pose while the IAL algorithm results still contain the solution.

6. Conclusion

In this paper a set membership approach has been presented to deal with localization problems in mobile robotics. This method, combining several interval analysis tools appears to be efficient in a real context. The algorithm makes it possible to perform a global localization and to handle kidnapping situations, even with outliers in the measurement set.

Then this method is compared to a MCL algorithm, which is mainly used to deal with the global localization problem. This comparison reveals that interval analysis can be an efficient alternative to this probabilistic approach. Even if the first iteration of the IAL algorithm costs more computation time than a classical MCL, when considering an entire exploration mission the computation times of both algorithms are similar. Furthermore the proposed method is rigorous since it considers all the possible solutions regards to the localization problem and does not search a global minima that is assumed to be the solution.
