Supporting Information

ABSTRACT: A straightforward synthesis of a bis-(pyrrolo)tetrathiafulvalene (BPTTF)-based tetratopic ligand bearing four pyridyl units is described. The first example of a TTF-based self-assembled cage has been produced from this redox-active ligand through metal-directed synthesis with a cis-coordinated square-planar Pt(II) complex. The resulting cage corresponds to a trigonal-prismatic structure, as shown by X-ray crystallography. A UV–vis titration indicated that the electron-rich cavity can be used to incorporate one molecule of tetrafluorotetracyano-p-quinodimethane (TCNQF$_4$).

Coordinated-driven self-assembly has proven to be a very efficient strategy to reach host structures of various shapes and sizes, such as polygons and polyhedra, that are otherwise very challenging to reach through usual covalent chemistry. In addition, this methodology potentially allows one to tune the binding properties of the corresponding cavity by incorporating specific functionalities within the framework structure. Within this field, there are very few examples of self-assembled three-dimensional (3D) cages involving redox-active side walls, and the majority of those reported incorporate electron-acceptor ligands (typically of the 1,3,5-triazine or quinone family). To the best of our knowledge, functional metallo-supramolecular cages built from highly π-electron-donating side walls are unknown to date and would constitute a fascinating system that is complementary to previous supramolecular cages made from π-electron-accepting ligands. On the other hand, the π-donating ability of tetrathiafulvalene (TTF) derivatives is well-established, projecting this unit as a key redox building block and sizes, such as polygons and polyhedra, that are otherwise very challenging to reach through usual covalent chemistry. In this regard, we recently investigated the preparation of pyridyl units incorporated in the TTF derivative bis(pyrrolo)tetrathiafulvalene (BPTTF). This work has led to a 3D level (i.e., self-assembled cages) of striking importance in the design of cavities with addressable binding properties.

With this objective in mind, the tetrapyridyl-BPTTF ligand 3 (Scheme 1) was designed and synthesized through nucleophilic addition onto pyridine by a non-organometallic process. The reaction of BPTTF 1 with activated triflated pyridine generated in situ produced compound 2 in good yield, considering that four covalent bonds are formed concomitantly.

Scheme 1. Synthesis of Ligand 3

| Conditions: (a) pyridine (8 equiv), triflic anhydride (6 equiv), CH$_2$C$_2$H$_2$ -30 °C, 15 min, 46%; (b) tBuOK (10 equiv), THF, 45 min, 81%. |

46% yield after purification by SiO$_2$ column chromatography. Conversion to the target tetratopic ligand 3 in 81% yield was then carried out with 10 equiv of tBuOK in tetrahydrofuran (THF).

The tetrapyridyl-BPTTF ligand 3 was then engaged in a self-assembly process with the cis-(PE$_4$)$_2$Pt(OTf)$_2$ complex. Several discrete architectures would potentially be expected from this reaction, depending on the number of ligating units (i.e., 3) involved in the construction of the self-assembled product and/or on their respective orientation. Remarkably, the reaction of 3 with a 2-fold ratio of the Pt(II) complex in dimethyl sulfoxide (DMSO) at 75 °C converged within 2 h (as determined by $^1$H NMR monitoring), affording a single structure that was isolated by evaporation of the solvent. In particular, the corresponding spectrum condensed rapidly to a simple set of signals, as expected for a highly symmetrical structure (Figure 1). It is noteworthy that the α and β proton signals of the pyridyl units were strongly modified in comparison with those of the starting ligand 3. Indeed, in addition to a significant shift due to the nitrogen–Pt(II) coordination, splitting of both pyridyl proton signals of the pyridyl units existed in two different environments in the resulting complex.

This observation is assigned to the restricted rotation around the Pt–N bond because of steric constraints and suitably correlates to the case of the prismatic structure (Scheme 2). The NH singlet was also shifted significantly downfield in the complex (+0.18 ppm), and both the $^3$P and $^{19}$F NMR spectra exhibited a single signal, in accordance with the formation of only one species. Finally, a $^1$H diffusion-ordered spectroscopy (DOSY) NMR experiment showed only one alignment of

Scheme 2. Synthesis of the Trigonal Prism 4

Conditions: (a) cis-(PET)3Pt(OTf)2, DMSO, 75 °C, 2 h, quant.

Figure 3. Cyclic voltammogram of cage 4 [C = 6 × 10−4 M in acetonitrile containing 0.1 M NBu4PF6; scan rate 50 mV s−1; V vs Fc/Fc+; working electrode (GCE)].

Cyclic voltammetry of cage 4 was carried out in acetonitrile containing 0.1 M NBu4PF6. As shown in Figure 3, two successive oxidation processes were observed, and cage 4 presents good π-donating character. Both redox steps (E°1ox = 0.43 V; E°2ox = 0.62 V) are shifted to higher potentials relative to BPTTF 1 (E°1ox = −0.02 V; E°2ox = 0.23 V; Figure S13)10 and exhibit poor electrochemical reversibility. This observation is ascribed to a combination of electronic and structural features: (i) as shown by the X-ray structure, the through-bond communication to the metal centers via the pyridyl units and the accumulation of metal cations on the periphery of the redox BPTTF backbone contribute to a decrease in the π-electron-donating ability of 4 relative to BPTTF itself,11 and (ii) the rigidity of the 3D architecture contributes to a change in the kinetics of electron transfer during the electrochemical processes.

The binding ability of cage 4 was evaluated by a UV–vis titration with tetrafluorotetracyano-p-quinodimethane (TCNQF4−) in acetonitrile. This compound is a prototypical electron-poor guest that is prone to interact with an electron-donating cavity and (compared to TCNQ) is soluble in a wide range of solvents. Moreover, it presents a suitable size and geometry for inclusion within cage 4. Adding aliquots of TCNQF4− to an acetonitrile solution of the electron-donating receptor led to a progressive color change, assignable to the formation of a charge-transfer complex. New absorption bands appeared (Figure 4) at 752 and 849 nm, corresponding to the progressive formation of the TCNQF4− radical anion12 and at 690 nm, corresponding to the BPTTF radical cation.13 In addition, careful examination of the absorption spectra between 0 and 1 equiv (Figure S14) and 0 and 10 equiv (Figure 4) of added TCNQF4− showed the disappearance of the free receptor 4 (442 nm) with the concomitant evolution of a new band at 408 nm, accompanied by an isosbestic point. This observation indicates that only two species are in equilibrium, as expected for a 1:1 host–guest complex, and regarding the symmetrical character of the prismatic cavity, corroborates inclusion of the TCNQF4− unit within the cavity. This statement was further
confirmed by construction of the corresponding Job plot (Figure 4 inset), which shows 1:1 stoichiometry for the complexation between 4 and TCNOF$_2$.

An original and straightforward functionalization of BPTTF produces the tetrapotic ligand 3, which gives rise to 4, the first example of a 3D cage incorporating the electron-rich TTF framework. The latter is a fascinating and successful framework for binding an electron-accepting TCNOF$_2$ unit. This result opens promising perspectives as a complementary approach to the well-established use of electron-poor self-assembled receptors.
