## 10 Abstract

Sandy beaches are places of active organic matter mineralization due to water renewal providing 11 12 organic matter and electron acceptors in the porous and permeable sands. Recycled biogenic 13 compounds are efficiently transferred to the coastal marine environment via wave and tidal-driven 14 advective flows. The biogeochemical processes in beach aquifers were mainly studied in semi enclosed systems with low tidal amplitude, and with a connection to continental aquifers 15 16 contributing to solute fluxes to the coast from terrestrial groundwater. We present here the study of 17 a pocket beach isolated from terrestrial aquifers with a high tidal amplitude and a medium energy wave regime. In situ measurements, cross-shore profiles and vertical sampling were conducted 18 19 during several tidal cycles in spring and autumn. Cross-shore transects, obtained at low tide from 20 holes that represent a mixture of the upper 20 cm of the water saturated zone, showed 21 concentration gradients of redox and recycled compounds. Increase in pCO<sub>2</sub>, dissolved phosphate 22 and ammonium concentrations downslope revealed that more products from organic matter 23 mineralization accumulated in the lower beach. The related increase in total alkalinity downslope 24 indicated that the part of anaerobic processes in organic matter oxidation was higher in the lower 25 beach. Concentration and  $\delta^{13}$ C of dissolved inorganic carbon in pore waters suggested that the carbon mineralized in pore waters came from marine plant debris that were mixed with the sand. 26 27 Continuous probe records of dissolved oxygen saturation and vertical profiles revealed a tidally-28 driven dynamics of pore water in the first centimetres of the lower beach aquifer. Ventilation of pore 29 waters corresponded to wave pumping and swash-induced infiltration of seawater in the upper 10-30 20 cm of sediment. Nutrients and reduced compounds produced through organic matter 31 mineralization remained stored in pore water below the layer disturbed by wave. The flux of these 32 components to seawater is possible when this interface is eroded, for example when wave energy 33 increases after a less energetic period. The low extension of the studied aquifer, typical of pocket

beaches, limits the connection with continental groundwater. Both tidally-driven and wave-driven
 recirculation of seawater allows pocket beaches to be efficient bioreactors for marine organic matter
 mineralization. As such, they provide the coastal environment with recycled nutrients, and not new
 nutrients.

40

#### 41 **1.** Introduction

42

43 Almost one third of the world's ice-free shoreline is sandy (Luijendijk et al., 2018). Sandy 44 beach sediments are permeable and constitute unconfined aquifers where pore water can circulate. 45 Both terrestrial and marine forces drive underground water flows within beach sedimentary bodies. 46 Resulting submarine groundwater discharge (SGD) can be a significant source of dissolved ions, 47 nutrients, or contaminants to the coastal ocean (Sawyer et al., 2016; Slomp and Van Cappellen, 48 2004). Marine forces such as tidal pumping and wave-induced pressure gradients may induce fluid 49 flow into superficial permeable sediments (Ataie-ashtiani et al., 2001; Burnett et al., 2003; Moore 50 and Wilson, 2005). Along tidal coasts, seawater circulating through intertidal sandy beach sediments 51 can contribute to 90% or more of SGD and its associated geochemical signature (Li et al., 1999). 52 Hence, intertidal sandy beaches are the place of a large recirculation of seawater.

53 Sandy beaches generally have low sedimentary organic matter content (Boudreau et al., 54 2001). However, numerous studies have shown that they are very active places of remineralization 55 due to water renewal in the porous and permeable media providing organic matter and electron 56 acceptors, mostly oxygen from seawater (Anschutz et al., 2009; Billerbeck et al., 2006; Charbonnier 57 et al., 2013; Rocha et al., 2009; Santoro, 2010). When remineralization products are discharged into 58 the coastal ocean via recirculation of seawater, they eventually stimulate primary production and 59 may even cause harmful algae blooms and eutrophication on the inner shelf (Paerl, 1997).

Terrestrial hydraulic gradients result in a net fresh water input into the ocean when terrestrial groundwater mixes with recirculating seawater. The transition between saline pore water and fresh groundwater is called subterranean estuary (Li et al., 1999; Moore, 1999). The sharp interface between water masses of distinct salinities may represent a redox front, which has the potential to reduce nutrient and contaminant loading via groundwater through removal processes such as denitrification and phosphate sorption onto mineral surfaces (Charette and Sholkovitz, 2002; Kroeger and Charette, 2008; Slomp and Van Cappellen, 2004; Spiteri et al., 2006).

67

68 Beach hydrology and biogeochemistry response to groundwater, tidal, and wave forcing have 69 been extensively studied. Most of the field studies were conducted on relatively protected beaches 70 characterized by micro- (< 2m range) or meso-tidal regimes (2 to 4 m range), such as Waquoit Bay in 71 the western Cape Cod (Abarca et al., 2013; Gonneea and Charette, 2014), Cape Henlopen at the 72 outlet of the Delaware Bay (Hays and Ullman, 2007; Ullman et al., 2003), Magdalen Island (Couturier et al., 2017), Long Island sound (Tamborski et al., 2017), Tolo Harbour, Hong Kong (Liu et al., 2018) 73 74 and Ria Formosa (Rocha et al., 2009). The low-energy conditions occurring along these beaches 75 allowed scientists to deploy fragile sampling devices such as wells and in-situ monitoring probes. In agreement with hydrological models tested with similar low hydrodynamic conditions (e.g., Boudafel, 76 77 2000; Robinson et al., 2007), most of the aforesaid studies showed that a beach aquifer was often 78 characterized by a sharp transition zone between saline water and fresh water. This interface has a 79 steep slope and is generally located close to the low tide level. Infiltration of saline water into the 80 fresh groundwater in the tidal zone creates a reactive intertidal recirculation cell (Austin and 81 Masselink, 2006; Turner and Masselink, 1998; Bratton, 2010) that has been referred to as the upper 82 saline plume (e.g., Brovelli et al., 2007; Robinson et al., 2006; Santos et al., 2009; Vandenbohede and Lebbe, 2006). The magnitude of the tidal circulation cell and the associated transport of solutes 83 84 within the beach aquifer increase with higher tidal range, steeper beach slope and hydraulic conductivity as well as lower in-land hydraulic gradient (Li et al., 2009; Robinson et al., 2007). The 85 86 highly transient nature of the intertidal circulation cell over neap tide-spring tide and seasonal time 87 scales has been evidenced on a micro-tidal beach system (Heiss and Michael, 2014). Studies were 88 also carried out on high-energy beaches shaped by both a high mean tidal range and a high wave 89 exposure, such as the Truc Vert beach on the French Atlantic coast (Anschutz et al., 2009) or the 90 Spiekeroog Island off the North-West German coastline (Beck et al., 2017). In such hydrodynamic 91 context, seasonal erosion and accretion processes drastically reshape the beach profile (Castelle et 92 al., 2014). The unconfined aquifer of the intertidal zone generally consists of saline waters, the 93 intertidal salt water plume being deeper than in low-energy beaches. In the upper meters of the 94 intertidal aquifer, water has a short residence time due to the combined effect of efficient tidally 95 driven recirculation of saline pore water and high permeability of sands (e.g. Charbonnier et al., 96 2013). Circulation of saline pore water may drag parcels of brackish waters from meteoritic 97 groundwater mixture that may seep out the aquifer at the lower beach level (Buquet et al., 2016), 98 contributing to the flux of nutrients to the ocean (Anschutz et al., 2016).

99 Small pocket beaches are common worldwide along rocky shorelines (Short and Masselink, 100 1999). Undergoing limited sediment supply, pocket beaches present generally thin thickness of sand 101 deposited in the intertidal zone above the underlying bedrocks. Thus, the fresh water aquifers 102 connected to pocket beaches are generally restricted, making the offshore fresh groundwater discharge very weak. Consequently, pore water in tidal pocket beaches mainly consists of recirculating seawater. Here, the purely marine dimension of the biogeochemical reactor that a beach represents can be studied, with associated features and implications such as benthic-pelagic coupling and organic carbon respiration. To our knowledge, documentation on pocket beach pore water circulation coupled to biogeochemical processes is scarce, even missing in case of pocket beach with high tidal range.

109 In this paper, we report observations on a high tidal range pocket beach located on the Yeu 110 Island off the French Atlantic coast to investigate short-term (tidal scale) dynamics of biogeochemical compounds in pore waters at two contrasted seasons (spring and autumn) by way of detailed cross-111 112 shore, and vertical characterization of biogeochemical compounds in the sandy beach aquifer. Two 113 field campaigns were then conducted during periods of contrasted beach morphology, in October 114 2012 and April 2013. In October the beach displays the highest volume of sand stored in the 115 intertidal area during summer good weather accretion, whereas in April the beach is highly eroded 116 after winter storms. During each campaign, cross-shore profiles allowed to describe biogeochemical 117 processes from the upper to the lower beach. Vertical profiles obtained in the sandy beach aquifer from home-made vertical sampling collectors enabled to collect pore waters at several depths and at 118 119 different time after the tidal emersion. Finally, *in-situ* probes were buried in sediments to describe 120 the dynamics of dissolved O<sub>2</sub> during several consecutive tidal cycles.

121

## 122 2. Material and methods

#### 123 2.1. Study area

124 Located in the Bay of Biscay, Yeu Island is 8 km long and 3 km wide, elongated in a NW-SE direction about 20 km off French Atlantic coast (Fig. 1). The orthogneiss substrate of the island is 125 126 gently sloping from erosional cliffs along the southern coast that reaches 32 m at its highest point, to 127 nearshore bedrock outcropping at 0 to -2 m along the north-eastern coast (Durand et al., 2014). This 128 NE coast consists of a succession of sandy pocket beaches partitioned by hard rock headlands. Sandy 129 sediments form discontinuous lenses of less than 3 m thick over the very irregular bedrock. Aeolian dunes of low elevation (< 3 m) formed on the backshore are dominated by beachgrass (Ammophila 130 131 arenaria) and couch grass (Agropyrum junceum), and backed by marine pine and oak forests or by holiday cottages. Beach sediment is mostly composed of coarse to medium-sized siliciclastic particles 132 133 derived from the erosion of adjacent rocky outcrops, mixed with numerous shell debris, and thinly 134 overlays the orthogneiss substrate.

The studied area, so called Ker Chalon beach, is a 750 m long embayed coastline that features typical pocket beach characteristics: curved in plan between two headlands, low sediment supply. Ker Chalon beach, facing the mainland, is protected from the SW to NW Atlantic swell and

4

thus is subject to a moderate wave climate issue from the wave refraction around Yeu Island. Tides are semi diurnal and high-mesotidal to low-macrotidal with a mean range of 3.5 m (from 1.4 to 5.5 m). This hydrodynamical context allows Ker Chalon beach to display a large flat dissipative profile in the lower beach, comprised of fine sands developing under the swash at low tide, and a relatively narrow steep reflexive profile in the upper beach, with interlayers of fine sands, coarse sands and gravels (functioning under the breaking waves at high tide).

144

#### 145 2.2. Sampling collection

Seawater and pore water chemistry of the Ker Chalon beach was monitored during spring tide periods between the 16<sup>th</sup> and the 18<sup>th</sup> of October 2012, and between the 8<sup>th</sup> and the 11<sup>th</sup> of April 2013. The weather was rainy during both campaigns. For both campaigns, topography of the beach was measured cross-shore using an optical level, from the foot of the dune to the water line at low tide (Fig. 1). Profile elevations are given in reference to the Chart datum (mean lower low water).

For both campaigns, we applied three different techniques to get pore water properties of three successive days. To obtain a beach water table cross-shore transect, pore waters were sampled at the top of the water-saturated zone along parallel transects during the midday low tide (Fig. 1). In addition, pore waters were collected every 10 cm depth using 1-m long home-made vertical sampling collectors deployed at four sites at increasing distances from the dune foot. Autonomous O<sub>2</sub> probes were buried in the water-saturated sand for the whole duration of the field campaigns.

157 Pore waters from the top of the water-saturated zone were sampled according to Anschutz et al. (2009), and Charbonnier et al. (2013). Briefly, holes were dug every 10 m along a cross-shore 158 159 transect from the low-tide swash zone to the high-tide watermark. Seawater samples were collected 160 at the beginning of each transect. The water-saturated zone of sediment was reached with one 161 shovelful in the lower beach because sand was water-saturated up to the surface, whereas we had to 162 dig holes more than 0.5 m deep in the upper beach to reach the saturated zone. The first water that filled the bottom of the hole was removed with a polypropylene beaker. Due to the permeability of 163 164 sand, holes refilled slowly and the measurements were performed on the replenish water. 165 Temperature, salinity, pH, and dissolved oxygen saturation were directly recorded in the waters of 166 the excavated holes within one minute using WTW probes. The probes were calibrated before and 167 after each field campaign using an aerated solution (100% saturation) for the oxygen saturation, an 168 IAPSO seawater and deionized water for the salinity, and with NBS standard solutions (pH =4.01 and 169 pH = 7.00) for the pH. Oxygen and salinity probes were compensated automatically for *in-situ* 170 temperature. Waters were sampled using a 50-mL syringe and filtered through a 0.45 µm cellulose acetate syringe-membrane. One subsample was acidified with a 1% equivalent volume of 171 172 concentrated HCl for later analyses of dissolved inorganic phosphorus (DIP), dissolved iron and 173 manganese; another subsample was kept frozen until later analyses of other dissolved nutrients 174 (ammonium, nitrite, nitrate and dissolved silica (DSi)). We stored samples for the total alkalinity (TA) 175 in polypropylene bottles after filtration using a syringe equipped with glass fiber filter (0.7  $\mu$ m). The stable isotope signature of the dissolved inorganic carbon ( $\delta^{13}$ C-DIC) was measured in waters of the 176 first campaign. The  $\delta^{13}$ C-DIC samples were collected using 120 mL glass serum bottles sealed with a 177 rubber stopper and poisoned with 0.3 mL of HgCl<sub>2</sub> at 20 g  $L^{-1}$  to avoid any microbial respiration during 178 179 storage. Vials were carefully sealed taking care that no air remained in contact with samples. Vials 180 were also stored in the dark to prevent photo-oxidation. Several samples of the solid fraction from 181 the holes of the cross-shore transect were sampled in October 2012 in order to measure particulate 182 organic carbon (POC) and inorganic carbon (PIC), inorganic phosphorus and reactive particulate iron 183 and manganese concentrations.

184 Vertical profiles of pore water composition were obtained along a cross-shore transect at 185 two stations in October 2012 (stations 1 and 3) and at four stations in April 2013 (Fig. 1). Each station 186 was equipped with a pore water collector. The device was made with 1.2 m long and 10 cm diameter 187 PVC tube pierced every 10 cm on the height. Tygon® tubes (6 mm ID) were installed inside the PVC 188 tubes to connect each orifice to the top of the collector. The maximum dead volume was 30 mL for 189 the longest tubes. A 100  $\mu$ m mesh was put to the end of each tube in contact with sand to prevent 190 blocking during the sampling. Pore water collectors were positioned 5 m away from the cross-shore 191 transects described above. The upper station (station 4) was located 22 m off the dune foot in April 192 2013. The other stations were aligned cross-shore in the seepage face, 30 m or 20 m away one from 193 another (Fig. 1B). Station 3 was located in an area highly colonized by sandworms (Arenicola marina). 194 20 mL pore waters were collected with syringes trough each tube after discarding the corresponding 195 dead volume to rinse the sampling device. The sampling was always performed from the topmost 196 surface level to deepest levels to avoid vertical mixing of pore waters. Collectors were installed the 197 day before starting the sampling. Collection of pore waters started on the falling tide, just after the 198 emersion of each station, and was repeated every 2-3 h until immersion of each station during flood 199 tide. Oxygen saturation and temperature were measured immediately after pore water collection 200 using a FireSting O<sub>2</sub> meter equipped with microOptode and temperature probe (*PyroScience GmbH*). 201 Since these probes were available only during the second campaign (April 2013), oxygen saturation 202 was not measured in samples of vertical pore water collector during the first campaign (Oct. 2012). 203 The microOptode was calibrated daily for the oxygen saturation using an aerated seawater solution 204 (100% saturation). Oxygen microOptode was compensated automatically for water temperature. 205 Water samples were filtered through a 0.2 µm cellulose acetate syringe-membrane. One subsample 206 was acidified with 10  $\mu$ L of concentrated HNO<sub>3</sub> per 10 mL for later analyses of DIP, dissolved iron and 207 manganese, salinity and sulphate; another subsample was kept frozen until later analyses of208 dissolved inorganic nitrogen compounds (ammonium, nitrite and nitrate).

209 Autonomous probes equipped with a data logger were buried directly into the sediment 210 during 2 or 3 days at each campaign according to Charbonnier et al. (2016). Four stations were examined simultaneously along the cross-shore profile (Fig. 1B). In October 2012, station 1 and 2 211 212 were located in the lower beach at 102 and 72 m from the dune foot, respectively. Station 3 located 213 42 m from the dune was in a beach portion highly colonized by Arenicola marina. Station 4 was 214 located on the upper beach. In April 2013, the stations were located at the same distance from the 215 dune foot than the pore water collectors. The depth at which the probes were buried was in top 20 216 cm of the water table at low tide, i.e., at 20±5 cm depth in the lower beach and at 60±5 cm depth in 217 the upper beach. They measured continuously water pressure that is converted in water head 218 (CeraDiver sensors, Schlumberger<sup>®</sup>, precision of ±0.2 cm), salinity (STPS 100SI loggers, NKE 219 *instrumentation*; precision of  $\pm 0.1$ ), water temperature and dissolved oxygen concentration 220 (SDOT300 logger, NKE instrumentation, equipped with an Aanderaa optode model 3835; precision of 221  $\pm 0.05$  °C and  $\pm 5$  % respectively, without oxygen consumption or significant drift). Each probe 222 recorded pore water parameters *in-situ* every 2 min. Note that optodes were placed in water during 223 24 h before burial to moisten their foil as recommended by Aanderaa.

224

#### 225 *2.3. Analyses*

226 For pore waters sampled at the top of the water-saturated zone, the dissolved inorganic 227 compounds were analysed colourimetrically according to standardized techniques. NO<sub>2</sub><sup>-</sup> and NO<sub>3</sub><sup>-</sup> 228 were analysed according to Schnetger and Lehners (2014). Precision was  $\pm$  5% for NO<sub>2</sub><sup>-</sup> and  $\pm$  10% 229 NO<sub>3</sub><sup>-</sup>. DSi and DIP were measured by colorimetric procedures (Mullin and Riley, 1955; Murphy and 230 Riley, 1962). Ammonium and DIC (only for Oct. 2012 samples) were analysed with the FIA method 231 described by Hall and Aller (1992). The frozen subsample was defrosted on the day of the nitrite, 232 nitrate and ammonia analyses. The subsample was allowed to stand at room temperature for at least 233 24 h for depolymerization of silica before carrying out DSi analysis. The obtained precision of these 234 procedures was ± 5%. DIP was analysed on the acidified sample to prevent dissolved Fe(II) oxidative precipitation and subsequent post-sampling phosphate sequestration on Fe(III) phases. Dissolved 235 iron (Fe<sup>2+</sup>) was analysed by colourimetry by adding a ferrozine solution in an aliquot (Stookey, 1970). 236 237 Total dissolved manganese was determined colourimetrically using the Cd-TCPP complex according 238 to Madison et al. (2011) and Charbonnier and Anschutz (2019). Dissolved Fe and Mn were 239 determined with ± 5% precision.

For samples collected with vertical pore water collectors, nitrate, nitrite, and ammonium were measured using standard methods on a QuAAtro AutoAnalyzer (*Seal Analytical*). DIP was measured on the acidified sample by colourimetric method of Murphy and Riley (1962). Measurements of dissolved Fe, Mn, S and Na were performed by an ICP-OES ICAP 6300 Thermo-Fischer after a 50-fold dilution with a 1% ultrapure nitric acid. Analysed elemental sulphur was interpreted as sulphate since sulphide is volatile and was removed from the sample solution under acidic conditions. Salinity was calculated from sodium concentration.

247 TA of surface water table samples were analysed on filtered samples by automated electro-248 titration on 50 mL filtered samples with 0.1N HCl as titrant. The equivalence point was determined 249 from pH between 4 and 3 with the Gran method (Gran, 1952). Precision based on replicate analyses was better than ±5 µmol L<sup>-1</sup>. We calculated the partial pressure of CO<sub>2</sub> (pCO<sub>2</sub>) from TA, pH, and water 250 251 temperature measurements using the carbonic acid dissociation constants of Millero (1979) and the 252  $CO_2$  solubility from Weiss (1974) from the CO2SYS software (Lewis and Wallace, 1998). The  $\delta^{13}$ C-DIC 253 measurements were performed with the headspace technique using a isotope ratio mass 254 spectrometer coupled to an elemental analyser (EA-IRMS, Micromass IsoPrime) as described in 255 Gillikin and Bouillon (2007).

The grain-size distribution was measured using a Malvern laser diffraction particle size 256 257 analyser. The freeze-dried solid fraction was homogenised for chemical analyses. POC was measured 258 by infrared spectroscopy (LECO 200 C-S analyser) after removal of carbonates with 2M HCl from 50 259 mg powdered sample (Etcheber et al., 1999). Total particulate carbon was measured with the same 260 technique, on aliquots that were not acid-leached. PIC converted into CaCO<sub>3</sub> was deduced from the 261 difference between total carbon and POC. Detection limit was 0.2‰. The precision of measurements 262 was better than 5%. One gram crushed bulk sediment was leached with a 1N HCl solution to extract 263 reactive P, Fe, and Mn adsorbed on particles and precipitated as oxide, carbonate, and phosphate minerals (Anschutz et al., 2005; Kostka and Luther, 1994). Extracted iron, manganese, and 264 phosphorus contents were analysed colourimetrically according to standardized techniques with ±5% 265 266 precision (Anschutz and Deborde, 2016; Charbonnier and Anschutz, 2019).

267

#### 268 **3. Results**

#### 269 3.1 Beach morphology and sediment characteristics

Ker Chalon beach was 140 m wide at low tide in October 2012 and 130 m in April 2013 (Fig.
1). The difference was due to the spring tide amplitude, which was higher in October (4.8 m) than in
April (4.4 m). The beach profile changed between autumn 2012 and spring 2013. In autumn, the
beach showed a slightly convex to almost linear profile with a relatively steep gradient (7%) normally

274 resulting from summer aggradation. At 20 m from the dune foot, an erosional step of about 0.5 m 275 high was dug at the upper limit of wave run-up at high tide. This kind of feature in the upper 276 foreshore indicated the beginning of the winter erosion processes. The upper part of the beach was 277 eroded in April relative to the measurements carried out 6 months earlier. In spring, the beach 278 showed a concave profile with a slope break at 30 m from the dune foot, dividing the beach into two 279 distinct parts. The upper foreshore was 2 m below the topographic profile measured in October with 280 a slope of 17%, whereas the very flat lower foreshore displayed a dissipative morphodynamic beach 281 state with a slope of 2%. A source of seeping waters appeared at the slope break at low tide. The 282 lower beach remained always wet during tidal emersion. A continuous longshore zone of 5 to 10 m 283 width located at the upper part of the seepage face was highly inhabited by Arenicola marina both in 284 October and April (Fig.1), as evidenced by the presence of 2 to 10 fecal mounds per m<sup>2</sup>. The bedrock, 285 located at several decimetres below the topographic surface was not reached with the sampling 286 devices.

287 The particle size showed a large degree of heterogeneity between the upper and the lower 288 beach. The upper beach was composed of very permeable coarse sands and gravels, whereas the 289 surface sediment of the seepage zone, which constituted the main part of the studied beach, 290 consisted of well sorted particles composed of fine sand with a median grain size of 166±10  $\mu$ m 291 (Table 1) and a POC concentration of 0.20 $\pm$ 0.08% (166 $\pm$ 70  $\mu$ mol g<sup>-1</sup>), and a CaCO<sub>3</sub> content of 292 18.2 $\pm$ 4.6% (15167 $\pm$ 3833 µmol/g). Reactive inorganic Fe, Mn, and P concentrations were 48.6 $\pm$ 3.5 μmol g<sup>-1</sup>, 1.21±0.20 μmol g<sup>-1</sup>, 12.1±2.8 μmol g<sup>-1</sup>, respectively (Table 1). Sediment colour was light olive 293 294 grey (5Y 7/2) over the first 10 cm and grey (5Y 5/1) below. Hydraulic conductivity was not measured 295 in sands of the Ker Chalon beach but several empirical formulae allow to estimate this parameter 296 based on grain size distribution (Vienken and Dietrich, 2011). The USBR formula (Vuković and Soro, 1992) gave 2.4 m d<sup>-1</sup> whereas the Seelheim (1880) formula gave 8 m d<sup>-1</sup>. Ker Chalon beach is thus an 297 298 original example of an aquifer with a high tidal range, medium energy, gentle slope and medium 299 permeability.

300

#### 301 3.2. Water head measurements

As expected, water head levels increased during flood and decreased during ebb (Fig. 2). In the seepage zone of the lower beach (stations 1 to 3), water level was almost constant at low tide during emersion of the stations (Fig. 2), because the whole sediment column remained saturated with water. For these three stations, the water head was the sediment surface. In the upper beach (station 4), the water head slowly decreased as sediment emerged.. The drop in water level occurred in the porous medium due to the exfiltration of water downslope. It decreased continuously until the flooding of the next tide. The upper beach sediments were unsaturated in water down to 80 cm atlow tide (Fig. 2).

310

#### 311 *3.3. Temperature and salinity*

312 Seawater and pore water temperature was relatively constant, around 16 °C in October 2012 313 and between 9 and 11 °C in April 2013. Pore water salinity remained close to 34, which was similar to 314 the value measured in seawater (Fig. 3). Some surface pore waters showed lower values around 30. 315 Vertical profiles from collectors indicated that salinity remained around 33-34 in the middle part of the beach, at stations 2 and 3 (Fig. 4). Nevertheless, brackish waters were detected in April 2013 in 316 317 the upper beach below 1 m depth (station 4 with salinity around 30) and below 40 cm depth in the 318 lower beach (station 1 with salinity down to 23). Profiles were steady during time series of sampling 319 with pore water collectors (Fig. 4). Continuous measurements with probes located in the upper part 320 of the water-saturated zone also showed constant (±1) salinities, except at station 4 in April 2013, 321 where slightly lower salinities were recorded after emersion period (not shown on Fig. 2).

322

#### 323 3.4. Dissolved oxygen records

324 Waters collected along cross-shore profiles in the superficial part of the water table showed 325 a decrease in oxygen concentration from the upper beach to the lower beach (Fig. 3). A similar trend 326 was observed for both investigated seasons. In the upper beach section near the dune foot, oxygen 327 saturation of sediment pore water varied between 80% and 100% whereas most of the values were 328 between 20% and 40% in the lower beach section (Fig. 3). These values from holes dug in the sand 329 represented pore water samples that integrated the upper decimetre of the water table. In April 330 2013, the vertical profiles determined from pore water collectors showed that oxygen concentration 331 decreased with depth and reached a value lower than 20% below 40 cm depth at stations 1 and 2 332 (Fig. 4). This clearly showed that the sediment was divided into two parts. An upper part was enriched in dissolved O<sub>2</sub>, and a lower part, corresponding to the grey sand, was depleted in dissolved 333 334 O<sub>2</sub> and almost anoxic. Time series during emersion showed that the oxic layer displayed redox 335 oscillations, with values close to 100% saturation just after emersion, and a rapid decrease at a rate 336 of about 10–15% saturation per hour (Fig. 4). Vertical profiles were more scattered at station 3 337 inhabited by the sandworms Arenicola marina. They also showed a decrease in  $O_2$  saturation during 338 emersion, but waters remained oxic down to 1 m depth (Fig. 4). At station 4, the water table 339 deepened during emersion and pore waters remained oxic. *In-situ* probes recorded oxygen changes 340 during whole tide cycles (Fig. 2). They were placed in the transition zone between oxic and anoxic sediments. Probes were mainly in the anoxic part of the sediment at station 1 and at station 2 in 341 342 October 2012 (Fig. 2). In April 2013 at station 2, the probe buried at 20 cm depth recorded redox 343 oscillations, which showed an oxygen saturation decrease after emersion reaching values below 5%, 344 in agreement with pore water collector sample data. The probe also showed that oxygen level increased abruptly about 1 or 2 hours after the start of sediment immersion in the swash zone. The 345 346 maximum value remained below 25%, and this value was reached approximately 2 to 3 hours after 347 high tide (Fig. 2): redox oscillations followed the tidal cycle with a delay of a few hours at depth. In 348 addition, we observed a second peak of dissolved O<sub>2</sub> that occurred at low tide slack water on the 349 decreasing shoulder of the main peak. Such double-peaks were also observed at stations 3 and 4 (Fig. 350 2). At these stations, oxygen saturation also changed with tide and presented oscillation of 10% 351 amplitude.

352

### 353 3.5. Nutrients

354 The cross-shore profiles of dissolved nutrients ( $NO_2^-$ ,  $NO_3^-$ ,  $NH_4^+$ , DIP, DSi) of October 2012 355 and April 2013 had similar shapes and showed relatively low temporal variability (Fig. 3). Pore waters 356 at the top of the water table showed opposite cross-shore profiles for nitrate and ammonium (Fig. 3). 357 Pore water nitrate concentrations in the upper beach and in the zone inhabited by Arenicola marina were higher than in seawater. Most of the values were between 20 and 40  $\mu$ M (Fig. 3). NO<sub>3</sub><sup>-</sup> 358 359 remained below 10  $\mu$ M in the lower beach. Vertical pore water profiles of NO<sub>3</sub><sup>-</sup> showed values similar 360 to those measured in the holes of the cross-shore profiles (Fig 3 and 4). Time series of depth profiles 361 during emersion showed that nitrate concentration in deep pore waters did not change. However, 362 we did observe some changes in  $NO_3^-$  concentration in the top 20 cm of the sediment (Fig. 4). 363 Immediately after the station was exposed, the surface pore waters had a nitrate concentration close 364 to that of seawater. Afterwards, the concentrations returned to the values found deeper, so that 365 vertical profiles became homogeneous a few hours after emersion until the next immersion (Fig. 4). 366 Nitrite concentrations were often close to the detection limit, except at the bioturbated station 3, 367 where concentrations up to 5  $\mu$ M were measured in surface pore waters (Fig. 3 and 4). Waters of 368 surface table along the cross-shore transects were characterized by increasing gradients of 369 ammonium, DIP, and DSi, from the upper beach to the low tide swash zone (Fig. 3). Ammonium 370 reached 100  $\mu$ M in the lowest part of the beach, downstream from station 1 (Fig. 3). Vertical pore 371 water profiles of NH<sub>4</sub><sup>+</sup> showed mean concentrations similar to those measured in holes (Fig. 3 and 4). 372 As with nitrate,  $NH_4^+$  profile time-series between emersion and flood showed changes in the surface 373 sediment with concentrations going from the value of seawater to the value measured deeper after a 374 few hours (Fig. 4). DIP concentrations were around 10  $\mu$ M in holes of the lower part of the beach, 375 whereas they were close to seawater concentration in upper beach pore waters (Fig. 3). Here again, depth values from vertical profiles were similar to those from the holes, with concentrations close to 376 377  $2 \mu$ M at the investigated stations (Fig 3 and 4). Dissolved Si cross-shore profiles had the same shape

as DIP profiles (Fig. 3). DSi concentration was below 10  $\mu$ M in seawater and in holes of the upper beach, whereas a concentration of 50  $\mu$ M was reached in holes of the lower beach.

380

#### 381 *3.6. Other redox species*

382 In the cross-shore profiles, concentrations of dissolved Fe and Mn higher than seawater 383 values were found in pore waters depleted in dissolved oxygen, in the lower part of the beach (Fig. 384 3). Presence of dissolved Fe above 10  $\mu$ M occurred more particularly in samples depleted in 385 dissolved nitrate (Fig. 3). Hence, dissolved Fe concentration was close to seawater values in the bioturbated zone of the beach and in the upper beach, and Fe and Mn concentrations reached up to 386 387 75  $\mu$ M and 8  $\mu$ M, respectively, in holes of the lower beach. Vertical pore water profiles of the 388 stations 1 and 2 showed that dissolved Mn and Fe were absent in the top 20 cm sediments, and up to 389 3 and 6  $\mu$ M below (Fig. 4). Sulphate was measured in samples from pore water collectors. Sulphate 390 concentrations were close to the value expected from the salinity measurement, with values 391 between 27 and 28 mM at salinity close to 33, but some low sulphate deficit relative to salinity 392 occurred in pore waters of stations 1, 2, and 3 in April 2013 samples (not shown).

393

#### 394 *3.7. Carbon*

395 Parameters linked to carbonate chemistry were only measured in waters collected in holes of 396 cross-shore transects because the required water volume for analyses was too high to do it on 397 samples collected with pore water collectors. These parameters were similar for the three replicate 398 cross-shore transects realized during each campaign (Fig. 5). They also showed comparable trends in 399 October 2012 and in April 2013. TA of seawater was 2.3 mM (Fig. 5). Values measured in cross-shore 400 transects were close to seawater value in the permeable upper beach. TA increased up to 4 mM in 401 the seaward direction. The pH of seawater was close to 8.0Fig. 5. Minimum values were 0.2 pH unit 402 below seawater value in pore waters of the lower beach, except near the low tide mark in the profile 403 of April 11<sup>th</sup> 2013, in which the minimum value was 7.4 (Fig. 5). pCO<sub>2</sub> calculated from pH and TA was 404 in equilibrium with the atmosphere in seawater samples (close to 400 ppm) (Fig. 5). Values were 405 higher in pore waters with a pCO<sub>2</sub> value varying roughly between 800 and 2000 ppm. Interestingly the lower beach pore water of April 11<sup>th</sup> reached a pCO<sub>2</sub> of 5000 ppm (Fig. 5).  $\delta^{13}$ C-DIC was only 406 measured in samples of October 2012 (Fig. 5). Seawater  $\delta^{13}$ C-DIC value was 0.15 ‰. It was lighter 407 408 (more negative) in pore waters than in seawater. These pore waters with low  $\delta^{13}$ C-DIC values were 409 associated with high TA, with a minimum value of -7.92 ‰ measured in the sample with the highest 410 TA value (Fig. 5).

411

#### 412 4. Discussion

#### 413 *4.1. Physical context of the beach*

The Ker Chalon beach aquifer was mainly composed of saline water (Fig. 3), and did not have an underlying terrestrial groundwater body, as in most of the beaches studied. The main reason is that the Ker Chalon beach aquifer has a limited vertical extent. It is a sand lens (< 3 m thick) lying on the crustal bedrock, which prevents the intrusion of terrestrial groundwater in the tidal zone. The beach aquifer is mostly recharged by tidally driven recirculation of seawater. In addition to tidal forcing, waves increase the penetration of saline waters in the beach aquifer (Robinson et al., 2014).

Some brackish waters were evidenced in the lower beach, more particularly in April 2013 (Fig. 4), suggesting that some fresh water may be occasionally carried with the recirculating salt water. The freshwater mixed with recirculating seawater could be provided by meteoric waters infiltrating the low backshore dune bordering the beach.

424

#### 425 4.2. Vertical and horizontal gradients of biogeochemical compounds

426 There was a significant difference in temperature between October 2012 (15-16°C) and April 2013 (9-12°C). However, the profiles shown in Figures 3, 4 and 5 did not indicate sufficient 427 differences to interpret the results in terms of seasonal changes. The shape of vertical profiles looked 428 429 like well-known diagenetic profiles of marine sediments, where oxidized dissolved compounds were 430 present in pore waters close to the sediment surface (Fig. 4). Their concentration decreased with 431 depth, and reduced and recycled compounds accumulated at depth (Fig. 4). This was particularly true 432 at stations 1 and 2 located in the lower part of the beach. In these stations, ammonium, dissolved Fe, 433 and Mn concentrations increased below 20 cm depth, when dissolved O<sub>2</sub> and nitrate dropped to low 434 values (Fig. 4). These results suggest that sediment organic matter was oxidized through reactions in 435 which the available terminal electron acceptor that yielded the maximum energy was used, as 436 encountered in diffusion-dominated marine sediment (Froelich et al., 1979). At stations 4 and 3, 437 located in the upper part of the beach, sediment remained oxic, and reduced compounds such as 438 dissolved Fe and Mn kept concentrations close to those of seawater, below 2 µM, down to a depth of 439 1 m (Fig. 4). Nitrate concentration in these stations was higher than the value of seawater. As the 440 pore water salinity was similar to that of seawater, higher nitrate concentrations were most likely the 441 result of oxic mineralization of sedimentary organic matter (Charbonnier et al., 2013).

442 Cross-shore transects also showed horizontal concentration gradients of redox and recycled 443 compounds across the beach (Fig. 3). Waters of the upper beach were well oxygenated. In the lower 444 beach, the presence of reduced compounds and high concentrations of recycled nutrients indicated 445 that organic matter was mostly mineralized through anaerobic processes such as denitrification, 446 reduction of Mn and Fe oxides, and sulphate reduction. N:P ratio deduced from pore water NH<sub>4</sub><sup>+</sup>:DIP 447 ratio varied between 10 and 15 in holes of the lower part of the beach and in the vertical profiles of 448 station 1, suggesting that the mineralized organic matter was of marine origin. Increase in  $pCO_2$  (as 449 well as DIP and  $NH_4^+$ ) downslope the cross-shore transect (Fig. 5) clearly indicated that more 450 products from organic matter mineralization accumulated in the lower part of the beach. The related 451 increase in TA downslope suggests that the part of anaerobic processes in organic matter oxidation 452 was higher in the lower beach, as anaerobic processes create alkalinity (Kempe, 1990; Soetaert et al., 453 2007; Thomas et al., 2009). Denitrification and ammonification, when ammonium is not 454 subsequently nitrified, produce alkalinity (Abril and Frankignoulle, 2001). Both processes generate 455 one mole of TA per mole of nitrogen involved in the reaction. Sulphate reduction was suggested by a 456 sulphate deficit in the pore water of some samples and the grey colouration of sediments below a 457 few cm in depth, indicative of the presence of authentic iron sulphides. This process produces two 458 moles of TA per mole of sulphate reduced to S(-II) species, either escaping to the atmosphere when 459 sediments are exposed at low tide (Kristensen et al., 2000), or buried as Fe-sulphide. Fe(III) and 460 Mn(III,IV) oxide reduction is a net source of alkalinity if reduced Fe(II) and Mn(II) do not precipitate 461 again in the sediment. Carbonate mineral dissolution is also a source of alkalinity. However, this 462 process is not in agreement with the observed increase in pCO<sub>2</sub> and the decrease in  $\delta^{13}$ C-DIC (Fig. 5). 463 DIC added in pore water shifted the isotopic signature to negative values, suggesting that this 464 additional DIC came from a lighter source of carbon. Marine carbonates have a relatively heavy 465 signature close to 0‰, whereas organic matter has a negative signature. In addition, a graph showing 466 the evolution of alkalinity as a function of DIC shows a slope of 0.9 (Fig. 6A). This slope reflects the 467 stoichiometry of the predominant reactions controlling dissolved carbonate chemistry and thus can 468 be used to infer which reactions control dissolved carbonate chemistry (Cai et al. 2003; Liu et al. 469 2017). This slope would be 2 if the increase in alkalinity was due to the dissolution of carbonates. A 470 slope close to 1 is compatible with denitrification and sulphate reduction processes. All of these 471 results strongly suggest that the carbon added to the interstitial waters came from anaerobic 472 mineralization of sedimentary organic matter. This result means that the studied beach is a source of 473 alkalinity, as are larger systems such as the Wadden Sea intertidal zones (Beck et al., 2008, Santos et 474 al. 2015). Therefore pocket beaches may account for the alkalinity budget of coastal ocean, and as a 475 net total alkalinity generation setting, they have the potential to increase the capacity of the coastal 476 ocean buffer and the uptake of atmospheric carbon dioxide (Hu and Cai, 2011; Brenner et al., 2016; 477 Voynova et al., 2018).

478 Respiration processes in the beach aquifer occur when labile organic matter is present. A 479 Keeling-like diagram, where  $\delta^{13}$ C-DIC is plotted vs. 1/DIC concentration (Pataki et al., 2003), was used 480 to determine the isotopic composition of the organic carbon source respired in beach sediments. 481 Concentration and  $\delta^{13}$ C-DIC in pore waters could be explained by a mixture of seawater DIC with a 482 lighter source of additional DIC with a mean isotopic signature of -12.2‰±0.6‰ (Fig. 6B). This value 483 is less negative than marine phytoplankton isotopic signature (-22.7‰±0.8; Dubois et al., 2012) and 484 is close to the isotopic value of marine and saltmarsh angiosperms (-11.9‰±1.4; Dubois et al., 2012), as well as macroalgae such as seaweeds (-18.8‰±2.6; Dubois et al., 2012) from neighbouring rocky 485 486 shores and Ulva sp. (-11.1‰±1,8; Riera et al., 1996), suggesting that the carbon mineralized in pore 487 waters came from the sea or the seashore, and not from land sources, such as terrestrial higher 488 plants and river SPOM (-28.0%±1.3; Dubois et al., 2012). It may have resulted from marine plant 489 debris left on the beach at high tide (also known as wracks) mixed with the sand during seasonal 490 erosion-accretion episodes or sand remobilization due to waves. Wracks, of which small piles have 491 been observed on the beach, may have represented here a source of labile organic matter as 492 observed in other beach aquifers (Dugan et al., 2011; Lastra et al., 2018).

493

#### 494 *4.3. Pore water residence time*

495 The role of water residence time on biogeochemical processes was pointed out in several 496 studies focussing on seawater recirculation (e.g., Billerbeck et al., 2006; Waska et al., 2019). The studied transects covered oxic to anoxic redox-conditions as it has been described for other beaches 497 (e.g. Reckhardt et al., 2015). The existence of the well-developed horizontal redox zonation from oxic 498 499 to anoxic conditions towards the sea in the beach aquifer implied either that organic matter fuelling 500 biogeochemical reactions was not the same, or that physical controls differed between the upper 501 and the lower beach. We have measured similar concentrations of organic matter along the transect 502 and we did not observe a gradient of  $\delta^{13}$ C-DIC end-member, suggesting that the origin of organic 503 matter was not the variable that explained the horizontal redox gradient. Field observation suggests 504 that water residence time was the main parameter that explained differences in biogeochemical 505 processes. The water table of the upper beach dropped at each low tide (Fig. 2), indicating that the 506 porous environment of the upper aquifer transiently filled with air was replenished with seawater at 507 each tide. This zone was infiltrated by well-oxygenated, low-nutrient seawater at each flood. During ebb tide, a part of the pore water was flushed towards the sea, leaving the sand water unsaturated 508 509 until depth around 80 cm at station 4 (Fig. 4). Deep layers of the upper beach aquifer that remained 510 water-saturated, sampled at low tide in holes and at the bottom of pore water collectors, had a 511 residence time sufficiently long to become enriched in dissolved nitrate, slightly enriched in DIP and 512 DSi, but not long enough to become anoxic.

513 The upper beach acted as the recharge zone of the beach aquifer. Seawater infiltrated the 514 beach face during flood faster than it discharged during ebb. Hence, the time-averaged beach water 515 table was higher than the mean sea level (Turner et al., 1997), creating a seaward hydraulic gradient 516 at low tide. Pore water circulated into the beach aquifer and seeped out in the lower intertidal zone 517 (Horn, 2006; Robinson et al., 2007; Xin et al., 2015). In the Ker Chalon beach, the seepage face

15

518 represented almost all the beach, from 40 m off the dune foot to the low tide mark located 100 m 519 seaward farther. The fact that the water table height was almost equal to the lower beach surface is 520 characteristic of fine sand beaches (Horn, 2006). The upper part of the seepage face, at 40 m from 521 the dune foot corresponded to the portion that was highly inhabited by Arenicola marina. It was oxic 522 down to 1 m depth (Fig. 4), suggesting that this section of the beach received pore waters from the 523 recharge zone as a result of the seaward hydraulic gradient that occurred at low tide. In this portion 524 of the beach, oxygen concentrations showed a reverse profile after 5 hours of exposure with 525 concentrations at depth between 40 and 90 cm that were higher than those between 10 and 40 cm 526 (Fig. 4). The ventilation of the deep layer was not due to Arenicola marina bioirrigation because 527 worm activity does not reach the sediment deeper than 40 cm depth (Meysman et al., 2005). Deep 528 ventilated waters most likely came from the recharge zone and flowed towards the lower beach 529 aquifer during low tide.

530 Oxic waters were only present in the first decimetres of the lower beach aquifer (Fig. 4). 531 Below 30 cm depth, concentrations of reduced compounds (dissolved Fe and Mn) and metabolic 532 products (ammonium, DIP, DSi) increased seaward. This suggests that waters flowing seawards in the 533 beach aquifer became depleted in dissolved oxygen and nitrate because these waters were old. 534 Oxygen was consumed and denitrification occurred before waters were flushed through tidally-535 driven recirculation. Considering the value of hydraulic conductivity estimated from grain size of fine 536 sand (between 2.4 and 8 m  $d^{-1}$ ), and the slope of the beach, the Darcy velocity was between 1 and 3 537  $cm h^{-1}$ . This meant that pore water covered only a few centimetres seawards during each low tide. 538 This is in agreement with the fact that profiles from pore water collectors sampled three consecutive 539 days at each campaign remained relatively constant below 30 cm depth. The estimated Darcy 540 velocity implied that anoxic pore waters found in the lower beach aquifer originated from seawater 541 that entered the upper beach sand several months before sampling. Such a low renewal of pore 542 water in the lower beach explains why waters became anoxic and enriched in metabolic products. It also suggests that rain waters that infiltrated the sand in the upper beach and in the dune aquifer 543 544 were not totally diluted in saline pore water because of its low renewal. This may explain why we 545 found brackish pore waters at some places of the lower beach. The fresh water end-member 546 probably originates from rain events that occurred several months before seeping.

547

#### 548 *4.4. Tidal-scale dynamics*

549 Continuous probe records of dissolved oxygen saturation and vertical profiles of some 550 chemical components revealed a tidal dynamics of pore water in the first centimetres of the lower 551 beach aquifer. Results showed that dissolved oxygen concentration increased abruptly when flood 552 tide reached the studied stations (Fig. 2). Thus, sudden ventilation of pore waters corresponded 553 probably to wave swash-induced infiltration of seawater. Several studies have determined the 554 dynamics of the swash zone moisture. Studies focusing on the estimates of swash infiltration into unsaturated sand (e.g. Heiss et al., 2014; Masselink and Turner, 2012; Steenhauer et al., 2011) 555 556 showed that a water table mound thus formed was a consequence of a rapid rise in water content 557 during rising tide. Seawater inflow was the highest near high tide as observed at station 4 located 558 close to the high-tide water mark (Fig. 2). In most of the beach aquifer, from station 3 to the lower 559 part of the beach, the sediment remained water-saturated up to the sediment surface at low tide. In 560 this situation, the beach could behave as an impermeable surface (Packwood, 1983). Nevertheless, our observations suggest that swash-induced dynamics consisted of a replacement of pore waters by 561 562 seawater in the upper 10–20 cm of sediment. It has been shown that waves caused cyclic infiltration-563 exfiltration corresponding to vertical flow across the sediment surface in saturated sediments 564 (Turner and Masselink, 1998). More generally, pressure gradients due to wave generate fluxes across 565 the sediment-water interface as observed in many different contexts (Huettel et al., 2014; Riedl et 566 al., 1972; Santos et al., 2012; Shum and Sundby, 1996). Therefore, ventilation of the upper 10–20 cm 567 sediment surface was the result of pore water-seawater mixing in the swash zone during flood and ebb tides, and also during the period of immersion, due to wave-induced pressure gradients (wave 568 569 pumping). The increase in the intensity of this pump resulted in better irrigation and ventilation of 570 the submerged sands and a deepening of the redox front (McLachlan and Turner, 1994; Riedl et al., 571 1972). Probes deployed at stations 1 and 2 showed very low concentrations of dissolved oxygen (Fig. 572 2), probably because they were placed at a depth at the limit of the influence of wave-induced water 573 mixing. However, the periodic ventilation due to swash and immersion at each high tide could be 574 seen clearly (Fig. 2).

575 The evolution of concentration profiles during emersion was observed from the hourly 576 sampling of pore waters (Fig. 4). Pore waters collected at the beginning of beach exposure period 577 were similar to seawater in the upper 10-20 cm. In this layer, oxygen concentration decreased rapidly except at the very surface of the sediment, which remained in contact with atmosphere. This 578 observation has been made for the three periods of low tide monitored the 9<sup>th</sup>, 10<sup>th</sup> and 11<sup>th</sup> April 579 580 2013, confirming that ventilation of pore waters occurred at each high tide. The rapid shift in oxygen 581 concentration at low tide corresponded to a loss of more than 100  $\mu$ M in less than 5 hours at 10 cm 582 depth at stations 1, 2, and 3. This change could not alone be explained by *in-situ* aerobic respiration 583 process confined in the upper part of the aquifer, because such an efficient respiration rate would 584 also have occurred at high tide, which was not the case. Oxygen loss due to aerobic respiration would 585 have been consistent with an increase in nitrate concentration, which was also not the case at stations 1 and 2 (Fig. 4). In fact, oxygen and nitrate profile monitoring showed that surface pore 586 587 waters evolved within a few hours from concentrations close to those of seawater just after 588 exposure to values close to those found at depth, suggesting that during emersion, concentration 589 changes were mostly due to a transport process, and not to reactions. Solute transport on a distance 590 of several centimetres in the sandy porous media may take about 1 month for transport by molecular 591 diffusion (Huettel et al., 2014, 1996), which is much longer than observation. Therefore, the fluxes 592 we observed were most likely explained by vertical advection of pore water. This flow can be 593 interpreted as the vertical component of the seepage flow due to tidally-driven circulation of pore 594 water at low tide (Chassagne et al., 2012; Robinson et al., 2007; Rocha et al., 2009; Xin et al., 2015). 595 Dissolved Fe, Mn, ammonium, and DIP showed constant profiles during emersion at stations 1, 2, and 596 3 (Fig. 4). These dissolved species had a concentration close to that of seawater in the upper 20 cm, 597 and higher concentrations below. The gradient did not move upward during emersion (within the 10-598 cm vertical resolution of our sampling), unlike dissolved oxygen and nitrate. This suggests that the 599 reduced compounds did not cross the redox boundary imposed by the depth of oxygen penetration 600 determined by the intensity of the waves and swash.

601 To summarize, the coupling between wave and tidally driven circulation on the wide seepage 602 face corresponded first to a mixture with seawater of the 10–20 cm upper pore water during flood 603 and immersion due to swash and wave pumping, and second to a 10-20 cm advective upward flux of 604 waters at low tide due to pore water circulation in the intertidal circulation cell (Fig. 7). Seeping 605 waters were mostly seawater that had filled the pores in the first decimetre of the beach aquifer 606 during the previous high tide due to waves. Nutrients and reduced compounds produced during 607 organic matter mineralization accumulated in pore water below the interface between the layer 608 disturbed by wave mixing and the undisturbed aquifer. The flux of these components to the 609 seawater may have occurred each time this interface was eroded, for example when wave energy 610 increased after a period of lower energy.

611

#### 612 **5. Conclusions**

613 The Ker Chalon beach is a pocket beach with fine sand that forms a small unconfined 614 permeable aquifer. Pore water chemistry monitoring shows that biogeochemical processes are 615 coupled to tidally-driven recirculation. Pore water composition is progressively modified along the 616 intertidal cross-shore transect because of the production and consumption of chemical components 617 due to marine organic matter mineralization. Aerobic processes occur in the upper part of the beach, 618 where pore water are young. Seawards, in the seepage area, dissolved oxygen becomes depleted 619 and anaerobic processes continue the mineralization of organic matter in older pore waters. 620 Therefore, the porous media located a few decimetres below the beach face shifts from oxic in the 621 upper beach to anoxic in the lower beach. In this beach, mineralization of organic matter creates a horizontal redox stratification, not a vertical one as commonly observed in benthic environments,because of tidal pumping.

Wave-driven advection of pore water ventilates the upper part of the aquifer along the whole cross-shore transect. A vertical redox gradient occurs in the lower beach mostly because of this advection. The redox boundary that coincides with the depth of wave influence becomes shallower during emersion due to tidal pumping, inducing a flux of pore water toward the beach face. Then, the water that seeps out the aquifer at low tide is mostly composed of oxic pore water that recently entered the upper aquifer through wave pumping.

630 This mechanism implies that fluxes of nutrients and of reduced compounds occur mostly 631 during immersion when redox boundary is eroded by wave-pumping after it has been shifted 632 upwards during the previous low tide. Therefore, an increase in wave amplitude may deepens the 633 mixed layer and may enhance the flux toward seawater of biogeochemical solutes issuing from 634 organic matter recycling. The low hydraulic conductivity of Ker Chalon beach does not permit a rapid 635 renewal of pore water in the aquifer. However, both tidally-driven and wave-driven recirculation of 636 seawater allow the beach aquifer to be a bioreactor for marine organic matter mineralization that 637 prevents accumulation of organic matter and metabolic products. The low extension of the studied 638 aquifer, typical of pocket beaches, limits the connection with continental groundwater, unlike many 639 other tidal environments, even if recirculating seawater comprises a high percentage of SGD (Slomp 640 and Van Cappellen, 2004; Knee and Paytan, 2011; Anschutz et al., 2016; Tamborski et al., 2017). As 641 such, the beach provides the coastal environment only with recycled nutrients, and not with new 642 nutrients. This is a distinguishing feature of pocket beaches. This general characteristic of pocket 643 beaches, however, should not blind us to the fact that the temporal and spatial properties of SGD are 644 site-specific (e.g., Urish and McKenna, 2004; Pain et al., 2019). As a result, it is difficult to extrapolate 645 across all pocket beaches from a single example. Other pocket beaches now deserve to be studied 646 and compared to the example of Yeu island described here.

647

#### 648 Acknowledgments

The authors gratefully acknowledge several colleagues and students who helped during the different field experiments: Cyril Ohandja Guindir, the students of the 3d year of Licence Géosciences et Environnement (promotion 2013-2014), Eric Bénéteau, Anthony Barbe, Sabrina Bichon, Ludovic Wnuczynski, Stéphane Bujan. This project was financially supported by the French National Program ESTAFET (CNRS - INSU).

## 908 Figure captions

909

Figure 1: Map of the Yeu Island and location of the Ker Chalon beach (A). Graphical representation of
the sampling site on the tidal beach (B). Cross-shore topographic profiles obtained in October 2012
and April 2013 with the position of pore water collectors (C)

913

Figure 2: Dissolved oxygen saturation and water head recorded in October 2012 and April 2013 in sediment of the Ker Chalon beach at the station along the cross-shore transect (Fig. 1). Data were obtained from autonomous probes buried in the upper part of the water-saturated aquifer at low tide.

918

Figure 3: Salinity and concentrations of dissolved O<sub>2</sub>, nitrate, nitrite, ammonium, dissolved manganese, dissolved iron, inorganic phosphorus (DIP), and dissolved silica (DSi) in pore waters from cross-shore transects of the Ker Chalon beach in October 2012 (left column) and April 2013 (right column). Transects were replicated three times at low tide during each campaign. The position 0 m corresponds to the base of the dune. Seawater values are represented by a star at the 150 m position.

925

926 Figure 4: Vertical profiles of salinity and concentrations of dissolved O<sub>2</sub>, nitrate, nitrite, ammonium, 927 dissolved manganese, dissolved iron, and inorganic phosphorus (DIP) in pore waters from pore water 928 collectors deployed on the Ker Chalon beach in October 2012 (left) and April 2013 (right). Sampling 929 was replicated several times during one emersion period to monitor the evolution of measured 930 parameters in an hourly time scale. Such sampling was repeated at two or three low tides during 931 each campaign; the evolution was the same each time. Profiles presented here are those from samples collected in October 17<sup>th</sup> 2012, and April 11<sup>th</sup> 2013. The positions of pore water collectors 932 933 indicated on Fig. 1 are represented by vertical bars.

934

Figure 5: Total alkalinity, pH, and pCO<sub>2</sub> values in pore waters from cross-shore transects of the Ker Chalon beach in October 2012 (left) and April 2013 (right), and  $\delta^{13}$ -DIC in pore waters from October 2012. Transects were replicated three times at low tide during each campaign. The position 0 m corresponds to the base of the dune. Seawater values are represented by a star at the 150 m position.

940

Figure 6. (A) TA concentrations versus DIC, and (B) Keeling plot of Ker Chalon beach pore waters
collected in October 2012. The intercept at the origin of the Keeling plot gives the isotopic signature
of the source of the mineralized organic carbon that produces additional DIC relative to seawater DIC
concentration.

945

Figure 7: Schematic representation of hydrologic circulation during flow (left) and low tide (right) showing potential source contributing to ventilation of pore waters. 1: Parcels of meteoritic waters mixed with saline water; 2: Seeping of pore water at the slope break; 3: Vertical component of tidally-driven circulation pushing the redox gradient upwards. The dotted line indicates the boundary between the aquifer dominated by aerobic and anaerobic organic matter (OM) mineralization processes.. **FIGURE 1**
